#### Abstract

We design a new version of a cycler orbit between Earth and Mars (known as the Aldrin cycler) in which we use low thrust to reduce the encounter velocities. We show that by reducing the encounter velocities at both planets, the propellant needed by the taxis to perform hyperbolic rendezvous can be significantly reduced. If the V-infinity reduction is large enough, two-stage taxis can be used instead of three-stage taxis, thus further reducing the required injected mass to a low-Earth orbit (IMLEO) for a particular cycler trajectory. However, as the V-infinity decreases, the propellant expenditure for the cycler vehicle increases. Our trade studies (over seven synodic periods) show that $V$-infinity reductions can be effective in reducing the total IMLEO (i.e. cycler plus taxi) propellant for low-thrust Aldrin cycler missions.

## I. Introduction

NUMEROUS ways of transporting humans from Earth to Mars (and back to Earth) have been analyzed over the years. ${ }^{1-10}$ The simplest architecture is to directly launch from the Earth to Mars, land, and then repeat the process to come back to Earth. In this ("Direct") case a separate set of hardware and consumables is needed for each launch. Alternatives to direct launches are cycling trajectories. A common feature of all cyclers is the reuse of the cycling spacecraft, thus eliminating the need to re-launch most of the hardware. These cycling trajectories (or cyclers) have been discovered and studied since the 1960s. ${ }^{2-8}$ The most well-known among these cyclers is the Aldrin cycler. ${ }^{5-6}$

The Aldrin cycler comprises two mirroring trajectories. These are called the outbound cycler (or sometimes the "up escalator") and the inbound cycler (or the "down escalator"). ${ }^{5-6}$ The outbound cycler provides short (typically 6-month) trips from Earth to Mars, but take much longer (about 1.6 years) to return from Mars to Earth. The inbound cycler is the mirror image of the outbound, providing short return trips from Mars to Earth but having longer Earth-Mars transits. An architecture that uses the Aldrin cycler to transport people would take advantage of the short transfers of the inbound and outbound cyclers to reduce travel time between Earth and Mars. ${ }^{9-10}$ At each flyby, smaller spacecraft called "taxis" would ferry astronauts between the spacecraft on the cycler trajectory (hereafter "cycler vehicle") and the surfaces of the planets. The taxis then perform hyperbolic ${ }^{11}$ rendezvous with the cycler vehicles to safely complete the transfer of humans.

Unfortunately the hyperbolic rendezvous sometimes have very high $\mathrm{V}_{\infty}$ at Mars (ranging from about 6 $\mathrm{km} / \mathrm{s}$ to over $12 \mathrm{~km} / \mathrm{s}$ ). These high $\mathrm{V}_{\infty}$ make the hyperbolic rendezvous costly in terms of taxi propellant, especially at Mars. ${ }^{9-10}$ The rendezvous are more manageable at Earth for two main reasons: first, the $\mathrm{V}_{\infty}$ are lower ( 5 to $7 \mathrm{~km} / \mathrm{s}$ ), and second, the propellant is more easily obtained at Earth. In this paper, we design a modified low-thrust version of the Aldrin cycler with lower $\mathrm{V}_{\infty}$ at Mars. We expect to see a significant reduction in the taxi propellant usage, while accruing a moderate increase in the propellant used by the

[^0]American Institute of Aeronautics and Astronautics
cycler vehicles. We perform trade studies to show that this propellant trade leads to lower total IMLEO cost to maintain the cycling transportation system.

## II. Methodology

We use a low-thrust trajectory optimizer developed at Purdue University (based on earlier work by Sims and Flanagan ${ }^{12}$ called GALLOP. GALLOP stands for Gravity-Assist, Low-thrust Local Optimization Program. ${ }^{13-16}$ GALLOP transforms the trajectory optimization problem into a nonlinear programming (NLP) problem and maximizes the final spacecraft mass; it is driven by a sequential quadratic programming algorithm, SNOPT. ${ }^{17}$

The trajectory model in GALLOP divides each planet-planet leg of the trajectory into segments of equal duration. The thrusting on each segment is modeled by an impulse at the midpoint of the segment, with conic arcs between the impulses. Each leg is propagated half-way forward from the initial body and halfway backward from the final body. In order to have a feasible trajectory, one of the constraints that must be satisfied is that the forward- and backward-propagated half-legs must meet at a match-point in the middle of the leg. The planetary positions and velocities are determined using an integrated (or analytic) ephemeris such as the Jet Propulsion Laboratory's DE405.

The optimization variables in GALLOP include the following: 1) the impulsive $\Delta \mathrm{V}$ on each segment, 2) the Julian dates at the launch, flyby, and destination bodies, 3) the launch $\mathrm{V}_{\infty}$, 4) the incoming inertial velocity vectors at all of the postlaunch bodies, 5) the spacecraft mass at each body, 6) the flyby periapsis altitude at the gravity-assist bodies, and 7) the B-plane angle at the gravity-assist bodies. The optimization program can alter these variables to find feasible and optimal solutions of the given problem. A feasible solution means that the variables satisfy the constraints. These constraints include upper bounds on the impulsive $\Delta \mathrm{V}$ on each of the segments, the launch $-\mathrm{V}_{\infty}$ magnitude, and the encounter dates at the bodies. Within the feasible set of solutions, the optimizer can find a solution which maximizes the final mass of the spacecraft.

We have the choice to parameterize the encounter velocities in either cartesian or spherical coordinates (a choice we did not have when we attempted to design a low- $\mathrm{V}_{\infty}$ Aldrin cycler in 2002, when GALLOP , in its early stages of development, could only represent the $\mathrm{V}_{\infty}$ in cartesian coordinates ${ }^{15}$ ). If the coordinate system used is spherical, then GALLOP allows constraints on the magnitude, cone, and clock angles of the $\mathrm{V}_{\infty}$ vector. To reduce the $\mathrm{V}_{\infty}$, we constrain the magnitude of the vectors (and leave the angles unconstrained) for each optimization run (while maximizing final spacecraft mass). We then gradually lower the upper bounds on the $\mathrm{V}_{\infty}$ magnitudes and re-optimize the result using the previous run as an initial guess.

The Aldrin cycler theoretically repeats forever because the positions of the spacecraft, Earth, and Mars in inertial space repeat every 14.95 years (seven Earth-Mars synodic periods). Therefore, to ensure that our modified Aldrin cycler retains its repeatability, we must constraint the total time-of-flight to 14.95 years. As we gradually lower the upper bounds on the $\mathrm{V}_{\infty}$ magnitudes, the (unconstrained) encounter dates also change, in part to accommodate the changing orbit shape. (Our experience is that Mars encounter dates typically move forward when Mars $\mathrm{V}_{\infty}$ are lowered.) As we progressively decrease the $\mathrm{V}_{\infty}$ upper bounds, the Mars flyby dates increasingly move forward in time; eventually we reach a point where further tightening of the $\mathrm{V}_{\infty}$ constraints results in a non-convergent optimization run. (When this happens, the typical run time increases from approximately 10 minutes to several hours on our Sun Blade 1000 workstation equipped with 1 gigabyte of memory.) We note that all of our resulting trajectories still have coasting arcs, suggesting that the $\mathrm{V}_{\infty}$ could be lower, because the vehicle has not exhausted all of its opportunity to thrust. The cases we present in this paper are thus suboptimal in terms of the lowest achievable $\mathrm{V}_{\infty}$ magnitudes, but are optimal in terms of final spacecraft mass (for the particular set of $\mathrm{V}_{\infty}$ constraints). Our main concern here is to show an improvement over previous designs.

Our cycler spacecraft is partially based on the vehicle design in Nock's studies. ${ }^{9-10}$ However, we choose to employ nuclear electric propulsion (NEP) on our cycler vehicle instead of solar electric propulsion (SEP), which was assumed in Nock's work. Our vehicle has the same thrust level as Nock's, but with higher specific impulse ( $\mathrm{I}_{\mathrm{sp}}$ ). We assume that our cycler vehicle has a dry mass of 50 metric tons (mt), with up to 25 mt of propellant. The cycler vehicle specifications are summarized in Table 1.

American Institute of Aeronautics and Astronautics

# Table 1. Cycler Vehicle Specifications 

| Gross Mass | 75 mt |
| :--- | ---: |
| Dry Mass | 50 mt |
| Thrust Level | 4.12 N |
| Specific Impulse | $6,000 \mathrm{~s}$ |

The taxi model from Nock is used to calculate the propellant savings that result from $\mathrm{V}_{\infty}$ reductions. An exponential curve-fit is used on the propellant vs $\mathrm{V}_{\infty}$ data from Nock to provide the following equation that calculates the propellant ( $\mathrm{M}_{\text {prop }}$, in kg ) required for the taxi to rendezvous with the cycler vehicle (for a given $\mathrm{V}_{\infty}$ in $\mathrm{km} / \mathrm{s}$ ) at Mars.

$$
\begin{equation*}
\mathrm{M}_{\text {prop }}=7281 \exp \left(0.275 \mathrm{~V}_{\infty}\right) \tag{1}
\end{equation*}
$$

The taxis are either two- or three- stage rockets, depending on the $\mathrm{V}_{\infty}$ value. For $\mathrm{V}_{\infty}$ less than $7.6 \mathrm{~km} / \mathrm{s}$, two-stage taxis are used. For $\mathrm{V}_{\infty}$ that are more than $7.6 \mathrm{~km} / \mathrm{s}$, three-stage taxis are required. A curve-fit similar to the one for taxi propellant is used for the taxi stages masses, which include the necessary augmentation tanks and expendable engines. The relationship between hardware mass ( $\mathrm{M}_{\mathrm{hard}}$, in kg ) and $\mathrm{V}_{\infty}$ (in $\mathrm{km} / \mathrm{s}$ ) is described by the following equation.

$$
\begin{equation*}
\mathrm{M}_{\mathrm{hard}}=451.77 \exp \left(0.344 \mathrm{~V}_{\infty}\right) \tag{2}
\end{equation*}
$$

To put the taxi propellant savings into a mission-design perspective, we convert the total propellant requirement (taxi and cycler vehicle combined) into the required injected mass to a low-Earth orbit (IMLEO). The IMLEO represents the propellant that must be launched from Earth to Mars (in the case of taxi propellant and propellant-related hardware) and from Earth to the cycler vehicle (to replenish its propellant reserve) every 15 synodic period to maintain the cycler transportation architecture. We calculate the IMLEO with the rocket equation, ${ }^{18}$ based on the following assumptions.

1. Taxi propellant and propellant-related hardware are sent to Mars via a low-energy orbit. This transfer is assumed to have completed in advance of the start of the cycler trajectory. The total $\Delta \mathrm{V}$ (the sum of Earth escape, trans-Mars injection, and direct Mars entry) is $7.1 \mathrm{~km} / \mathrm{s}$.
2. Cycler propellant is sent directly to the cycler vehicle from the low-Earth orbit. The total $\Delta \mathrm{V}$ is about $4.7 \mathrm{~km} / \mathrm{s}$ to rendezvous with the cycler.
3. The ratio of the inert mass to the propellant mass (for all $\Delta \mathrm{V}$ ) for is $16 \%$.
4. The specific impulse (for all $\Delta \mathrm{V}$, except the cycler's) is 450 seconds. We recall from Table 1 that the cycler has a specific impulse of 6,000 seconds.
5. All $\Delta \mathrm{V}$ (except the cycler's) are impulsive.

## III. Results

We designed a full 15-year Aldrin cycler (both inbound and outbound) with $\mathrm{V}_{\infty}$ that are (on the average) lower than the original unmodified Aldrin cycler.

## A. Modified Inbound Aldrin Cycler (using Low Acceleration)

Table 2 shows the trajectory itinerary of an inbound cycler with $\mathrm{V}_{\infty}$ constraints. The initial acceleration $\left(a_{0}\right.$, in $\left.\mathrm{m} / \mathrm{s}^{2}\right)$ of the thruster is

$$
\begin{equation*}
\mathrm{a}_{0}=5.5 \times 10^{-5} \tag{3}
\end{equation*}
$$

American Institute of Aeronautics and Astronautics

The first column lists the encounters with Earth and Mars and the sequence in the trajectory (for instance, E-1 is the first planetary encounter in the optimized trajectory, and the encounter is with Earth). The second column lists the encounter dates, and the last column shows the encounter velocities. For the inbound cycler, the Mars $\mathrm{V}_{\infty}$ are of particular interest, as the required taxi propellant (and propellant-related hardware mass) to perform hyperbolic rendezvous with the cycler vehicle for each Mars flyby is strongly dependent upon the $\mathrm{V}_{\infty}$, as shown by Eqs. (1) and (2). The final spacecraft mass (we recall the initial mass is 75 mt ) on this inbound cycler trajectory is about 65 mt . In contrast, the unmodified Aldrin cycler needs only 1 mt of propellant.

Table 2. Itinerary of an Inbound Cycler (with $V_{\infty}$ constraints) using Low Acceleration

| Body | Date $(\mathrm{mm} / \mathrm{dd} / \mathrm{yyyy})$ | $\mathrm{V}_{\infty}(\mathrm{km} / \mathrm{s})$ | Unconstrained $\mathrm{V}_{\infty}{ }^{\mathrm{b}}$ <br> $(\mathrm{km} / \mathrm{s})$ |
| :---: | :---: | :---: | :---: |
| E-1 | $5 / 22 / 2010$ | 5.513 |  |
| M-2 | $12 / 11 / 2011$ | $6.700^{\mathrm{a}}$ | 9.025 |
| E-3 | $6 / 25 / 2012$ | 4.945 |  |
| M-4 | $1 / 22 / 2014$ | $6.000^{\mathrm{a}}$ | 7.710 |
| E-5 | $8 / 4 / 2014$ | 5.236 |  |

| E-15 | $6 / 11 / 2025$ | 5.612 |  |

${ }^{\overline{\mathrm{a}}} \mathrm{V}_{\infty}$ are on upper bound constraints.
${ }^{\mathrm{b}}$ From Ref. 9 and 10; encounters occur on different dates.
As seen in Table 2, all of the Mars $\mathrm{V}_{\infty}$ are at their respective upper bounds. These upper bounds were obtained by a somewhat arbitrary process; they simply represent the lowest $\mathrm{V}_{\infty}$ we could obtain before the optimizer failed to converge. We started our $\mathrm{V}_{\infty}$-constraining process by selecting the encounters with the highest $\mathrm{V}_{\infty}$ values $^{9,10}(\mathrm{M}-2, \mathrm{M}-10, \mathrm{M}-12$, and $\mathrm{M}-14)$ shown in the last column of Table 2, and worked our way down until "all the tent poles were pounded into the mud." It is natural to conclude that our resulting cycler trajectory is not unique, and depends on the order in which we decreased the seven Mars $\mathrm{V}_{\infty}$. (This process of constraining $\mathrm{V}_{\infty}$ and re-optimizing is a challenging optimization problem on its own right and is not addressed in this paper.)

Due to the complexity of the Aldrin cycler, a trajectory plot (which tends to be "busy") is not the best way to visualize the orbits. Instead, we show a "radial distance plot," which illustrates the radial distances (from the Sum) of the spacecraft and the two planets. Encounters are denoted by solid dots on the plot. Figure 1 shows the radial distance plot of the optimized inbound cycler.

Figure 1. Radial distance plot of the $\mathbf{V}_{\infty}$-constrained inbound cycler.
Three curves are shown in Fig. 1. The lowest curve represents the orbit of the Earth, and the smallamplitude oscillation is due to the Earth's (comparatively) small eccentricity. Mars' orbit and the cycler trajectory are similarly represented in the graph. The elapsed time from the beginning to the end of the trajectory in Fig. 1 is roughly 15 years, or 7 Earth-Mars synodic periods. Because the inertial alignments of Earth, Mars, and the cycler vehicle at the beginning and the end (of the interval shown) are nearly the same, the cycler trajectory displayed in Fig. 1 would theoretically extend ad infinitum (with very little changes in the trajectory characteristics).

Table 3 shows the same inbound cycler trajectory compared to the unmodified Aldrin cycler (i.e., without $\mathrm{V}_{\infty}$ constraints). The first three columns are the same as the ones in Table 2; with Earth encounters removed (we only show the Mars encounters because the taxi propellant calculation for the inbound cycler is only dependent on the Mars $\mathrm{V}_{\infty}$ ). The changes in the encounter dates are shown in the fourth column (to demonstrate that the modified trajectory does not deviate too much from the timings of the original Aldrin cycler). Finally, the changes in the $\mathrm{V}_{\infty}$ and the associated taxi propellant savings are shown in the last two columns of the table.

Table 3. Comparison of with $\mathbf{V}_{\infty}$-constrained Trajectory with unmodified Aldrin Cycler (Inbound Cycler)

| Encounter | Date <br> $(\mathrm{mm} / \mathrm{dd} / \mathrm{yyyy})$ | $\mathrm{V}_{\infty}$ <br> $(\mathrm{km} / \mathrm{s})$ | $\Delta$ Date <br> $($ days $)$ | $\Delta \mathrm{V}_{\infty}$ <br> $(\mathrm{km} / \mathrm{s})$ | Taxi Propellant <br> Savings $(\mathrm{mt})$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| $\mathrm{M}-2$ | $12 / 11 / 2011$ | 6.700 | -28 | -2.325 | 49 |
| $\mathrm{M}-4$ | $1 / 22 / 2014$ | 6.000 | -24 | -1.710 | 27 |
| $\mathrm{M}-6$ | $4 / 6 / 2016$ | 6.200 | -13 | -1.016 | 15 |
| $\mathrm{M}-8$ | $7 / 10 / 2018$ | 6.600 | -1 | -0.208 | 3 |

| $\mathrm{M}-12$ | $10 / 13 / 2022$ | 8.200 | -27 | -3.703 | 146 |
| $\mathrm{M}-14$ | $11 / 19 / 2024$ | 8.200 | -12 | -2.835 | 97 |

American Institute of Aeronautics and Astronautics

In Table 3, we note that 2-stage taxis (instead of 3-stage taxis) can now be used at M-2 and M-10, because their respective $\mathrm{V}_{\infty}$ have been reduced to below $6.7 \mathrm{~km} / \mathrm{s}$. Even though we were unable to decrease the $\mathrm{V}_{\infty}$ at M-12 and M-14 to lower than $8.2 \mathrm{~km} / \mathrm{s}$, the reductions in $\mathrm{V}_{\infty}$ ( $3.7 \mathrm{~km} / \mathrm{s}$ and $2.8 \mathrm{~km} / \mathrm{s}$, respectively) still result in very large decreases in taxi propellant requirement. We recall that the inbound cycler shown above needs about 10 mt of cycler propellant, while only 1 mt of cycler propellant is required by the unmodified outbound Aldrin cycler. However, we also note the dramatic reduction in the total taxi propellant ( 414 mt off of the 703 mt required by the unmodified inbound Aldrin cycler) with these $\mathrm{V}_{\infty}$ constraints. Overall, we consider this a favorable propellant trade. Table 4 lists the total IMLEO for these two versions of the inbound Aldrin cycler, we note that even though the cycler propellant expenditure increased ten-fold, the (approximately) $50 \%$ reduction in taxi propellant requirement still more than made up for this additional cost.

Table 4. Propellant IMLEO (per 7 synodic periods) Comparison

| Table 4. Propellant IMLEO (per 7 synodic periods) Comparison |  |  |  |
| :---: | :---: | :---: | :---: |
| Trajectory | Taxi Propellant <br> IMLEO $(\mathrm{mt})$ | Cycler Propellant <br> IMLEO $(\mathrm{mt})$ | Total IMLEO (mt) |
| Unmodified Aldrin <br> Cycler | 13,355 | 4 | 13,359 |
| Aldrin Cycler with <br> Reduced $\mathrm{V}_{\infty}$ | 6,486 | 39 | 6,525 |

Figure 2 shows the comparison of the radial distance curves of the $\mathrm{V}_{\infty}$-constrained trajectory (solid curve) and that of the unmodified Aldrin cycler (dashed curve).

Figure 2. Comparison of radial distance curves.
In Fig. 2 we note the significant reduction in the "overshoot" of the cycler curve at just prior to all Mars encounters (these reductions would not be easily seen on a trajectory plot), especially at M-2, M-4, M-10, $\mathrm{M}-12$, and M-14 (where the largest $\mathrm{V}_{\infty}$ decreases occur). These reductions in the overshoot decrease the angles between the cycler's and Mars' velocity vectors at encounters, thus resulting in lower $\mathrm{V}_{\infty}$. (Actually, the changes in encounter dates also provide some reductions in the $\mathrm{V}_{\infty}$, but to a lesser extent.) We recall that the inbound cycler shown here does not have the lowest achievable $\mathrm{V}_{\infty}$ values, in part due to the fact that our relatively low thrust level can only modify the orbit shape in a limited way.
B. Modified Inbound Aldrin Cycler (using High Acceleration)

We now increase the thrust level, doubling it to 8.24 N . The corresponding initial acceleration is

$$
\begin{equation*}
\mathrm{a}_{0}=1.1 \times 10^{-4} \tag{4}
\end{equation*}
$$

Table 5 shows one such resulting inbound cycler trajectory.
Table 5. An Inbound Cycler with High Acceleration ${ }^{\text {a }}$

| Encounter | Date <br> $(\mathrm{mm} / \mathrm{dd} / \mathrm{yyyy})$ | $\mathrm{V}_{\infty}$ <br> $(\mathrm{km} / \mathrm{s})$ | $\Delta$ Date <br> $($ days $)$ | $\Delta \mathrm{V}_{\infty}$ <br> $(\mathrm{km} / \mathrm{s})$ | Taxi Propellant <br> Savings $(\mathrm{mt})$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| M-2 | $11 / 10 / 2011$ | 5.000 | -59 | -4.025 | 69.37 |
| M-4 | $01 / 02 / 2014$ | 5.000 | -44 | -2.710 | 37.90 |
| M-6 | $03 / 18 / 2016$ | 5.000 | -32 | -2.216 | 28.74 |
| M-8 | $05 / 28 / 2018$ | 5.000 | -44 | -1.808 | 22.06 |
| M-10 | $07 / 29 / 2020$ | 5.000 | -57 | -4.704 | 90.61 |
| M-12 | $09 / 01 / 2022$ | 5.000 | -69 | -6.903 | 194.38 |
| M-14 | $09 / 28 / 2024$ | 5.000 | -64 | -6.035 | 145.79 |

Table 5 shows dramatic reductions in $\mathrm{V}_{\infty}$ values at all Mars encounters (all are below $6.7 \mathrm{~km} / \mathrm{s}$, thus twostage taxis can be used at all Mars encounters). The resulting reduction in taxi propellant is a staggering 589 mt (we recall that for the unmodified inbound Aldrin cycler, the taxi would need a total of 703 mt of propellant). The resulting total IMLEO for the inbound cycler shown in Table 5 is only $3,380 \mathrm{mt}$ (a $75 \%$ reduction of the IMLEO of the unmodified Aldrin cycler). Table 6 summarizes the IMLEO values for all the inbound cases considered.

Table 6. Inbound Cyclers Comparison

| Trajectory | Taxi Propellant <br> IMLEO (mt) | Cycler Propellant <br> IMLEO (mt) | Total IMLEO (mt) |
| :---: | :---: | :---: | :---: |
| Unmodified Aldrin <br> Cycler | 13,355 | 4 | 13,359 |
| Aldrin Cycler with <br> Reduced $\mathrm{V}_{\infty}$ (low <br> acceleration case) | 6,486 | 39 | 6,525 |
| Aldrin Cycler with <br> Reduced $\mathrm{V}_{\infty}$ (high <br> acceleration case) | 3,300 | 80 | 3,380 |

## C. Modified Outbound Aldrin Cycler (using High Acceleration)

Though not as crucial as in the inbound cycler, the Mars encounter $\mathrm{V}_{\infty}$ for the outbound case should be low as well. Low speed at Mars arrival increases the (width of the) entry corridor for the atmospheric entry, reduces the structural mass of the Mars taxi, and reduces the g-acceleration load on the crew. In the original outbound Aldrin cycler, the Mars arrival $\mathrm{V}_{\infty}$ is especially high (above $10 \mathrm{~km} / \mathrm{s}$ ) at the $\mathrm{M}-2, \mathrm{M}-4$, and M-6 encounters.

Using the same techniques described for the inbound cycler, we now bring these $\mathrm{V}_{\infty}$ down to $9.0 \mathrm{~km} / \mathrm{s}$. In this process, the spacecraft final mass is maximized while all Earth and Mars encounter dates are
allowed to move freely. The total time of flight is constrained to 15 years. Figure 3 shows the radial distance plot of an outbound cycler with $\mathrm{V}_{\infty}$ constrained. Though not shown in the figure, there are similar reductions in the overshoot as in the case of the inbound cycler.

Figure 3. Radial distance plot of the $\mathbf{V}_{\infty}$-constrained outbound cycler.
In this case we pick our cycler vehicle to be a scaled-up version of the Jupiter Icy Moons ${ }^{19}$ (JIMO) spacecraft with a specific impulse of $6,000 \mathrm{~s}$, so that

$$
\begin{equation*}
\mathrm{a}_{0}=1.1 \times 10^{-4} \tag{5}
\end{equation*}
$$

From the optimization of the entire seven consecutive missions, in which every Mars flyby $\mathrm{V}_{\infty}$ is at or less than $9.0 \mathrm{~km} / \mathrm{s}$ (compared to up to $11.5 \mathrm{~km} / \mathrm{s}$ in the original Aldrin Cycler), we find that the final mass at E15 is $91.42 \%$ of the initial mass at E1. This propellant requirement for the interplanetary vehicle is modest, considering that the JIMO spacecraft for the Jupiter mission consumes twice the propellant in half the duration. Table 7 shows the difference between the unmodified outbound cycler and the $\mathrm{V}_{\infty^{-}}$ constrained cycler.

Table 7. Comparison of $V_{\infty}$-constrained Trajectory (with high acceleration) to unmodified Aldrin Cycler (Outbound Cycler)

| Cycler (Outbound Cycler) |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
| Encounter | Date <br> $(\mathrm{mm} / \mathrm{dd} / \mathrm{yyyy})$ | $\mathrm{V}_{\infty}(\mathrm{km} / \mathrm{s})$ | $\Delta$ Date <br> (days) | $\Delta \mathrm{V}_{\infty}$ <br> $(\mathrm{km} / \mathrm{s})$ |
| $\mathrm{M}-2$ | $5 / 14 / 2012$ | 9.000 | 20 | -1.142 |
| $\mathrm{M}-4$ | $6 / 2 / 2014$ | 9.000 | 15 | -2.449 |
| $\mathrm{M}-6$ | $7 / 5 / 2016$ | 9.000 | 19 | -2.488 |
| $\mathrm{M}-8$ | $8 / 19 / 2018$ | 8.325 | 10 | -0.589 |
| $\mathrm{M}-10$ | $10 / 31 / 2020$ | 7.193 | -10 | 1.428 |
| $\mathrm{M}-12$ | $1 / 21 / 2023$ | 7.065 | -3 | 1.234 |
| $\mathrm{M}-14$ | $3 / 16 / 2025$ | 7.935 | 2 | 1.974 |

American Institute of Aeronautics and Astronautics

We note that in Table 7, several Mars encounters have their respective $\mathrm{V}_{\infty}$ lowered, while the others show increased $\mathrm{V}_{\infty}$ values. However, the main issue here is to bring down the most extreme $\mathrm{V}_{\infty}$ ( $\mathrm{M}-2, \mathrm{M}-4$, and M-6) from nearly $12 \mathrm{~km} / \mathrm{s}$ to a more manageable $9 \mathrm{~km} / \mathrm{s}$.

An optimal low-thrust trajectory is uniquely determined by the initial acceleration ( $\mathrm{a}_{0}$ ) and specific impulse ( $\mathrm{I}_{\text {sp }}$ ). Thus the propellant mass fraction is the same for a human vehicle of any size scaled from the robotic JIMO spacecraft, as long as these two parameters are the same. In our case, for instance, the propellant is about $10 \%$ of the initial mass. Let us now assume that $40 \%$ of the initial mass is accounted for as hardware mass that includes reactor, radiator, structure, propulsion systems, and propellant tank, leaving the remaining $50 \%$ of the initial mass for the payload. In other words, if a $20-\mathrm{mt}$ JIMO spacecraft were flown in our outbound Aldrin cycler, the vehicle can carry 10 mt of payload. For a spacecraft five times the size of JIMO, the payload mass is 50 mt , a reasonable value for a human mission. (For example, in NASA's Design Reference Mission, ${ }^{20}$ the interplanetary Earth Return Vehicle has a payload mass of 27 mt ; this payload mass includes crew cabin, life support system, consumables, etc., for six astronauts for an interplanetary flight of six months.) If ten times the size of JIMO is assumed-now requiring an electric power of 1 megawatt - the payload mass is 100 mt , making the interplanetary vehicle a comfortable haven for a large number of Mars explorers.

Of course, the payload capability will improve (percentage-wise) for a larger vehicle; a megawatt-class NEP vehicle will enjoy the lower specific mass (in $\mathrm{kg} / \mathrm{kW}$ ) of a large nuclear reactor and will probably employ thrusters with high thrust density. The selections of $a_{o}$ and $I_{s p}$ for the cycler vehicle, however, will involve a complicated interplay between the trajectory and hardware designs of the cycler vehicle, Earth taxi, and the Mars taxi.

## IV. Conclusion

With low-thrust propulsion, we mollify one of the biggest drawbacks of the Aldrin cycler-its high $\mathrm{V}_{\infty}$ values at Mars. We present several attractive trajectories with significantly reduced encounter velocities, and consequently, reduced total IMLEO. Even though the initial costs to get the cycler architecture going are not considered in this paper, our analyses show that the cost to sustain such a system (once it is up and running), can be dramatically reduced by decreasing the $\mathrm{V}_{\infty}$.
